Timing of acid weathering on Mars: A kinetic-thermodynamic assessment

Mikhail Y. Zolotov¹ and Mikhail V. Mironenko²

Received 19 December 2006; revised 23 February 2007; accepted 24 April 2007; published 27 July 2007.

[1] Weathering of olivine basalt by H₂SO₄-HCl aqueous solutions at the conditions of early Mars was investigated through numerical modeling in a system open with respect to CO₂ and O₂ only. The model includes dissolution rates of primary and secondary minerals and oxidation rate of aqueous Fe²⁺, as well as chemical equilibration among solutes, dissolved gases, and precipitates. The results reveal fast dissolution of Fe-Mg minerals at low pH, followed by preferential dissolution of plagioclase at higher pH. Correspondingly, solutions evolve from acidic, Mg-Ca-Fe²⁺-Fe³⁺-Al³⁺ compositions toward Na-rich alkaline fluids. The period over which neutralization and mineral precipitation may occur is shorter at higher initial pH, lower water to rock ratios, and larger mineral surface areas. Early stages of weathering are characterized by the formation of amorphous silica, goethite, and kaolinite, while zeolites and carbonates form considerably later at higher pH, where silica dissolves. Slow oxidation of Fe²⁺ causes precipitation of ferrous phyllosilicates. Comparison with Martian observations indicate that amorphous silica, Fe³⁺ oxyhydroxides, and Mg-, Ca-, and Fe-sulfates could have formed during multiple short-term episodes of acid weathering that were terminated by freezing and/or evaporation. Throughout history, impact generation of oxidants (e.g., O₂, SO₃, NO₂) caused formation of strong acids and incremental Fe²⁺ oxidation, the processes that are not efficient during O₂-deficient periods of volcanic degassing. Although impact-generated acid rainfalls could have caused intense weathering and erosion in Noachian time, dilution of acids and a prolonged existence of surface solutions favored local neutralization of solution, and formation, transport and deposition of clays.

1. Introduction

[2] The mineralogy and chemistry of Martian materials is consistent with aqueous weathering of primary mafic and ultramafic rocks. Sulfates, chlorides, carbonates, clay minerals, ferric oxyhydroxides, and silica phases detected in Martian soils and rocks usually form in aqueous environments [Clark *et al.*, 1982, 2005; Bell *et al.*, 2000; Bridges *et al.*, 2001; Ming *et al.*, 2006; Morris *et al.*, 2006; Glotch *et al.*, 2006; Ruff *et al.*, 2006; Bibring *et al.*, 2005, 2006]. Aqueous processes are supported by S-Mg correlations, the high and variable Br/Cl ratio in soils, altered, and sedimentary rocks, variable Fe³⁺, P, and Al contents, sulfate cements, as well as vugs and cracks filled with bright material in basalts [Rieder *et al.*, 2004; McSween *et al.*, 2004, 2006; Gellert *et al.*, 2006; Clark *et al.*, 2005; Haskin *et al.*, 2005; Ming *et al.*, 2006]. Because liquid water is not

stable on the present surface, alteration must have occurred earlier in history, consistent with morphologic evidence of fluvial activity and intense erosion [e.g., Carr, 1996; Craddock and Howard, 2002].

[3] Observations indicate a broad range of pH for aqueous weathering. Alteration in neutral to alkaline conditions is consistent with the presence of carbonates and smectites in Martian meteorites [Bridges *et al.*, 2001; Warren, 1998], and smectites in Noachian deposits [Poulet *et al.*, 2005]. The detection of jarosite in layered rocks at Meridiani Planum provides evidence for a low-pH environment [Klingelhöfer *et al.*, 2004; Clark *et al.*, 2005; McLennan *et al.*, 2005]. In Gusev crater, multiple signs of acid weathering are observed in excavated soils, surfaces of basaltic rocks, and altered rocks at Columbia Hills [Haskin *et al.*, 2005; Ming *et al.*, 2006; Morris *et al.*, 2006; Hurowitz *et al.*, 2006]. In particular, low-pH weathering in Gusev crater is supported by the high concentrations of P and the presence of Fe³⁺ sulfates in Paso Robles soil [Morris *et al.*, 2006; Ming *et al.*, 2006].

[4] Weathering by acid solutions includes rapid dissolution of major rock-forming minerals and basaltic glass, as inferred from field observations, experiments, and models [e.g., Murphy and Helgeson, 1989; White and Brantley,

¹School of Earth and Space Exploration, Arizona State University, Tempe, Arizona, USA.

²Vernadsky Institute of Geochemistry and Analytical Chemistry, Russian Academy of Sciences, Moscow, Russia.

1995; White, 2004; Brantley, 2004], as well as experiments, models, and field observations aimed at exploring Martian processes [Banin *et al.*, 1997; Tosca *et al.*, 2004; Fernández-Remolar *et al.*, 2004, 2005; Golden *et al.*, 2005; Hurowitz *et al.*, 2005, 2006; Schiffman *et al.*, 2006]. Among other actions, acidic H₂SO₄-HCl solutions convert igneous minerals to sulfates and chlorides, consistent with the chemistry and mineralogy of Martian materials [Clark and Van Hart, 1981; Banin *et al.*, 1992; Bell *et al.*, 2000; Bridges *et al.*, 2001; Clark *et al.*, 2005; Ming *et al.*, 2006; Gendrin *et al.*, 2005].

[5] Despite efforts to understand acid weathering in Martian environments [Burns and Fisher, 1990; Burns, 1993; Banin *et al.*, 1997; Tosca *et al.*, 2004; Golden *et al.*, 2005; Hurowitz *et al.*, 2005], the timing and conditions of alteration remain unknown. Here we developed a coupled kinetic-thermodynamic model to investigate interactions between acidic solutions and a Martian basalt. The model allows us to evaluate temporal changes in primary/secondary mineralogy and solution chemistry. Results are compared with Martian data and discussed in terms of origin and fate of acidic solutions in geologic history.

2. Model Description

[6] Irreversible chemical interaction of rock-forming minerals with an aqueous solution is modeled by coupling the kinetics of mineral dissolution with thermochemical equilibrium computations. The modeling is based on the following assumptions: (1) Formation of secondary solids occurs through dissolution of primary minerals, (2) oxidation of aqueous Fe²⁺ by dissolved O₂ is kinetically controlled, (3) all species in solution are in chemical equilibrium with each other, and (4) precipitation of secondary minerals is controlled by mineral solubility and occurs faster than mineral dissolution, which is the limiting step in the process [Helgeson, 1968]. In other words, solution composition is controlled by dissolution rates of primary and secondary minerals, oxidation rates of Fe²⁺ solutes, equilibria among solutes, and equilibria between solutes and newly precipitated solids. At each time step, the mineral assemblage consists of unaltered primary minerals, previously formed secondary phases, and newly precipitated solids in equilibrium with solution.

[7] Weathering is modeled as a series of consecutive equilibrations in aqueous solution calculated at each time step. For each equilibrium computation, elemental mass balance is calculated from the chemical composition of aqueous solution at the previous step and current rates of mineral dissolution. The molar amount of a mineral (*i*) dissolved at each time step is calculated using

$$x_i = S_i r_i \Delta t, \quad (1)$$

where notations are presented in the outset. Minerals precipitated at previous time steps are designated as primary phases and subjected to dissolution, unless they are in equilibrium with the current solution. The duration of each time step is determined numerically from a specified molar amount of the fastest dissolving mineral. Therefore similar masses are introduced into solution during each time step.

[8] At the first time step, the surface area of primary minerals is calculated from specified grain sizes. Because only a fraction of a mineral's surface is exposed to solution, the parameter *F_s* is used for each mineral to simulate fissuring of grains, rock disintegration, effective porosity, etc. For subsequent time steps, surface areas of primary minerals are computed by taking into account shrinking grain sizes. Surface areas of secondary minerals are calculated from specified grain sizes and amounts of precipitates. This is a reasonable assumption for clay and hydroxide/oxyhydroxide phases that often possess preferred grain sizes in aqueous media. Correspondingly, the number of grains of secondary phases changes during weathering.

[9] For the same volume of mineral grains, total surface area of spherical grains is inverse proportional to their radius,

$$S_i = 3 V_i R_i^{-1}, \quad (2)$$

and combining equations (1) and (2) leads to the following expression:

$$x_i = 3 F_s V_i R_i^{-1} r_i \Delta t. \quad (3)$$

Although *F_s* can change in unknown ways during weathering, it is assumed to be constant.

2.1. Kinetics of Mineral Dissolution

[10] For each time step, rates of dissolution are calculated for the current pH and degree of disequilibrium of solution with respect to a dissolving mineral,

$$r_i = \left[K_{0H^+} (a_{H^+})^{b(T-T_0)+n_0} + K_{0H_2O} + K_{0OH^-} (K_W a_{H^+}^{-1})^m \right] \times \exp \left[\frac{Ea}{R} \left(\frac{1}{T_0} - \frac{1}{T} \right) \right] \times \left\{ 1 - \exp \left[p \left(\frac{\Delta G}{RT} \right)^q \right] \right\} \quad (4)$$

In equation (4), the first term in square brackets describes the pH ($-\log a_{H^+}$) dependence of the dissolution rate [Kump *et al.*, 2000; Brantley, 2004]. The term $[b(T - T_0) + n_0]$ defines the pH dependence of dissolution rate below pH of zero charged surface (~ 5 to ~ 10 [Kump *et al.*, 2000; Brantley, 2004]) as a function of temperature. The parameter *m* shows the pH dependence of rate at pH above that of zero charged surface. First two major terms in equation (4) designate an Arrhenius-like equation that describes the temperature dependence of the rate. The third major term is used to simulate the decrease in the rate of a dissolution reaction as chemical equilibrium is approached [Lasaga, 1981; Aagaard and Helgeson, 1982; Brantley, 2004]. The coefficients *p* and *q* are adjustable parameters obtained by fitting near-equilibrium kinetic data available for some minerals [Cama *et al.*, 2000; Brantley, 2004].

[11] Our model includes 42 one-component solids that can form. Six of them are considered as primary minerals and 14 are formed as secondary phases (Table 1). Parameters of equation (4) for these minerals are depicted in Table 2. For augite, we extrapolated dissolution data from pH 1–6 toward pH 0–8. The validity of this extrapolation is supported by the steady dissolution rate dependence at pH 2–10 for diopside [Brantley, 2004] and a similar rate

Table 1. Primary Minerals in Basalts and Secondary Phases Formed in Models for Acid Weathering^a

Mineral	Formula	Data Source ^b
Olivine (Fo ₇₃)	Mg _{1.46} Fe _{0.54} SiO ₄	
Bytownite	Na _{0.45} Ca _{0.55} Al _{1.55} Si _{2.45} O ₈	
Pigeonite	Ca _{0.188} Mg _{1.21} Fe _{0.557} Al _{0.03} Si ₂ O ₆	
Augite	Ca _{0.446} Mg _{1.01} Fe _{0.445} Al _{0.066} Si ₂ O ₆	
Orthopyroxene	Ca _{0.125} Mg _{1.35} Fe _{0.48} Al _{0.03} Si ₂ O ₆	
Magnetite	Fe ₃ O ₄	
Amorphous silica	SiO ₂	1
Goethite	α-FeOOH	4
Kaolinite	Al ₂ Si ₂ O ₅ (OH) ₄	1
Fe ²⁺ -saponite	Fe _{3.175} Al _{0.35} Si _{3.56} O ₁₀ (OH) ₂	7
Daphnite	Fe ₅ Al(AlSi ₃ O ₁₀ (OH)) ₈	3
Stellerite	Ca ₂ Al ₄ Si ₁₄ O ₃₆ · 14H ₂ O	6
Stilbite	Ca ₂ NaAl ₅ Si ₁₃ O ₃₆ · 16H ₂ O	6
Mg-saponite	Mg ₁₉ Al ₂ Si ₂₂ O ₆₀ (OH) ₁₂	5
Na-saponite	Na ₂ Mg ₁₈ Al ₂ Si ₂₂ O ₆₀ (OH) ₁₂	5
Na-montmorillonite	Na _{0.35} Mg _{0.35} Al _{1.65} Si ₄ O ₁₀ (OH) ₂	7
Dolomite	CaMg(CO ₃) ₂	1, 2
Calcite	CaCO ₃	1, 2
Siderite	FeCO ₃	1
Gypsum	CaSO ₄ · 2H ₂ O	4

^aMartian basalt EETA 79001, lithology A [McSween and Jarosewich, 1983] is used as a proxy for composition of rock silicates. Other minerals in the models are Ca-, Na-, Fe-beidellites, Ca-, Fe-montmorillonites, Ca-, Na-saponites, clinocllore, greenalite, laumontite, gibbsite, boehmite, ferrihydrite, hematite, magnesite, and K-, Na-, H₂O-jarosit. Thermodynamic data for clays minerals are from Vieillard *et al.* [2004], Wilson *et al.* [2006], and Wolery and Jove-Colon [2004].

^bThermodynamic data for minerals are from: 1, Helgeson *et al.* [1978]; 2, Plummer and Busenberg [1982]; 3, Holland and Powell [1998]; 4, Robie and Hemingway [1995]; 5, Wolery and Jove-Colon [2004]; 6, Fridriksson *et al.* [2001]; 7, Wilson *et al.* [2006]. For primary minerals, thermodynamic data are relatively unimportant because fates of these minerals are determined by dissolution kinetics.

pattern below pH 5.9–8.5 that corresponds to zero charged surfaces for single chain silicates [Kump *et al.*, 2000]. Kinetic parameters of augite are used for all Fe²⁺-bearing pyroxenes. Data for montmorillonite are applied to dissolution rates of saponites and beidellites. For zeolites, we used dissolution parameters for anorthite. In the model, the inter-

action of goethite with solution is controlled by its low and declining solubility at rising pH, thus an arbitrary dissolution rate is chosen to maintain such behavior. Since the effect of temperature on pH dependence is not well known [Kump *et al.*, 2000; Brantley, 2004], parameter *b* is set to 0.

2.2. Oxidation Kinetics of Aqueous Fe²⁺

[12] In the presence of dissolved O₂, dissolution of ferrous minerals should be followed by oxidation of aqueous Fe²⁺, which may be accompanied by precipitation of metastable and semicrystalline ferrihydrite, ~Fe(OH)₃, that dehydrates to goethite, α-FeOOH. Reactions (5)–(7) can represent the oxidation

at pH < 2.2, pH = 2.2–3.5, and pH > 3.5, respectively [cf. Singer and Stumm, 1970; Millero *et al.*, 1987; Langmuir, 1997]. We used equation (8) to characterize the oxidation rate below pH 8,

$$-d[\text{Fe}^{2+}]/dt = k_1 [\text{Fe}^{2+}] \times [\text{O}_2] + k_2 [\text{Fe}^{2+}] \times [\text{O}_2] \times [\text{OH}^-]^2, \quad (8)$$

where values in brackets stand for concentrations of solutes [cf., Singer and Stumm, 1970], and *k*₁ and *k*₂ are rate constants representing oxidation at pH below and above ~3.5, respectively. Equation (8) assumes pseudo-first-order behavior with respect to dissolved Fe²⁺. Temperature and ionic strength dependencies of *k*₂ were taken from Millero *et al.* [1987]. We assumed that *k*₁ has the same dependencies as *k*₂.

Table 2. Parameters of Equation (4) for Calculation Rates of Mineral Dissolution

Mineral	<i>E_a</i> , kJ mol ⁻¹	log(<i>K</i> _{0H+}), mol m ⁻² s ⁻¹	<i>n</i> ₀	log(<i>K</i> _{0H2O}), mol m ⁻² s ⁻¹	log(<i>K</i> _{0OH-}), mol m ⁻² s ⁻¹	<i>m</i>
Amorphous silica ^a	62.8	0	0	-11.0	-9.0	0.3

Montmorillonite ⁱ	38.9	-10.6	0.74	0	-11.6	0.39

^a*E_a* is from Rimstidt and Barnes [1980]; log(*K*_{0OH-}) and log(*K*_{0H2O}) are taken about one log unit higher than for quartz after Icenhower and Dove [2000]; *n*₀ is as for quartz. The coefficients for quartz are calculated from Brady and Walther [1990].

^bData are from Brantley [2004] and Brady and Walther [1989].

^cData are from Brantley [2004] for pH < 6.

^d*E_a* is from Blum and Stillings [1995]. Other parameters are estimated from Brady and Walther [1989].

^e*E_a* is taken as an average for silicates. Other parameters were obtained by Alekseev [2007] through approximation data from Kodama and Schnitzer [1973], Hamer *et al.* [2003], and Lowson *et al.* [2005]. Data are applied to daphnite and clinocllore.

^f*E_a* is from Wogelius and Walther [1992] for forsterite; log(*K*_{0H+}) and *n*₀ is interpolated on the basis of data for forsterite [Chen and Brantley, 2000] and fayalite [Wogelius and Walther, 1992]; log(*K*_{0H2O}) is evaluated on the basis of work by Pokrovsky and Schott [2000].

^gApproximated data from Cama *et al.* [2002], Huertas *et al.* [1999], Carrol and Walther [1990], Ganor *et al.* [1995], and Nagy *et al.* [1991] by Alekseev [2007].

^h*E_a* is from Sidhu *et al.* [1981]; log(*K*_{0H+}) and *n*₀ was obtained by Alekseev [2005] from the data of White *et al.* [1994] for the incongruent dissolution of magnetite (equation (11)).

ⁱApproximated data from Amram and Ganor [2005], Bauer and Berger [1998], Cama *et al.* [2000], and Huertas *et al.* [2001] by Alekseev [2007].

[13] We considered the kinetics of Fe^{2+} oxidation as consecutive dissolution and oxidation reactions, i.e., Fe^{2+} (in minerals) $\rightarrow \text{Fe}^{2+}$ (aqueous) $\rightarrow \text{Fe}^{3+}$ (aqueous). The bulk oxidation rate can be expressed as

$$-d[\text{Fe}^{2+}]/dt = k_3 - k_4[\text{Fe}^{2+}], \quad (9)$$

where $k_3 = \sum_i r_i S_i \nu_i$ is the bulk rate constant of zero-order dissolution reactions for ferrous minerals containing ν_i atoms of Fe^{2+} per formula unit. The rate constant, k_4 , for oxidation of aqueous Fe^{2+} species at current pH, a fixed concentration of dissolved O_2 , temperature, and ionic strength is evaluated with equation (8) and data from *Singer and Stumm* [1970] and *Millero et al.* [1987]; $k_4 = [\text{O}_2] \times (k_1 + k_2[\text{OH}^-]^2)$. Integrating equation (9) gives the expression for the molar amount of Fe^{2+} oxidized at each time step

$$\Delta[\text{Fe}^{2+}] = \left(\frac{k_3}{k_4} - [\text{Fe}^{2+}]_0 \right) \times [1 - \exp(-k_4 \Delta t)], \quad (10)$$

where $[\text{Fe}^{2+}]_0$ is the initial concentration of Fe^{2+} -bearing species taken from the preceding time step. We used equation (10) to calculate the amount of oxygen added to the solution at each time step to participate in oxidation. Then, the model calculates chemical equilibrium in solution, producing new concentrations of Fe^{2+} and Fe^{3+} aqueous species and amounts of precipitated ferric minerals. Although the system is declared as open with respect to O_2 , specified atmospheric P_{O_2} values were only used to calculate the oxidation rate constant k_4 in equation (9). Note that in our model dissolution of magnetite also contributes ferric ions to solution and affects mass of goethite formed.

2.3. Thermodynamic Calculations, Input Data, and Model Limitations

[14] The thermodynamic block of the model is based on the GEOCHEQ code [*Mironenko et al.*, 2000], which uses the Gibbs free energy minimization method to calculate chemical equilibrium in solution-gas-solid systems. Thermodynamic properties of solutes are mainly from *Shock et al.* [1989, 1997], and data for minerals are mainly from *Helgeson et al.* [1978] and *Holland and Powell* [1998]. Thermodynamic data for clay minerals are specified in Table 1. Note that thermodynamic data for nontronite from *Wolery and Jove-Colon* [2004] may not be correct [*Bethke*, 1996].

[15] Calculations were performed for 0°C in the system H-O-S-Cl-C-Mg-Ca-Al-Si-Na-Fe, which was open with respect to CO_2 and O_2 . The Martian achondrite EETA 79001 (lithology A) studied by *McSween and Jarosewich* [1983] was used as a proxy for mineralogical composition of Martian olivine basalt (see Table 1). The modeled rock consists of six minerals in mol/kg rock: olivine (Fo_{73}), 2.69; bytownite (An_{55}), 2.55; pigeonite, 0.37; augite, 0.37, orthopyroxene, 0.33; and magnetite, 0.07. In contrast to EETA 79001 mineralogy, all opaque minerals are represented by magnetite. For case study modeling, grain size was taken as 0.2 mm for silicates and 0.05 mm for magnetite. For

primary minerals, the fractions of the exposed surface area (F_s) were taken as 0.01. Secondary minerals had grain sizes of 1 μm and were entirely exposed to solution. This is a good proxy for clay minerals, at least [*Meunier*, 2005].

[16] The case study modeling was performed for initial aqueous solutions that contained 0.05 moles H_2SO_4 and 0.0096 moles HCl per kg of water, yielding pH of 1.2. These and other solutions correspond to a S/Cl molar ratio of 5.2, consistent with the composition of Martian soils at landing sites of Vikings 1 and 2, Mars Pathfinder, and the Spirit rover [*Clark et al.*, 1982; *Foley et al.*, 2003; *Gellert et al.*, 2006].

[17] To simulate a termination of weathering by consumption of liquid water, we modeled freezing and evaporation for the specific times of solution evolution. The calculations were performed for the H_2O - SO_4 -Cl- CO_3 -Na-Ca-Mg-Fe system with the FREZCHEM model [e.g., *Marion*, 2002; *Marion et al.*, 2003], which uses Pitzer approach to calculate water activity and activity coefficients of solutes in concentrated solutions. Note that ferric species do not present in the FREZCHEM model because of lack of experimental data.

[18] Conceptual limitations of the coupled thermodynamic-kinetic model are related to neglecting (1) mass exchange with the surrounding environment (except O_2 and CO_2), (2) supersaturation of secondary phases and kinetics of precipitation, (3) differences in grain shape and F_s among minerals, (4) changes in grain shapes and F_s during weathering, (5) possible formation of metastable and amorphous phases (except silica), and (6) coatings by secondary minerals. The reliability of results is affected by high uncertainties or absence of (1) thermodynamic data for many clay minerals, zeolites, and some salts, (2) grain sizes, shapes and F_s for secondary minerals, and (3) questionable dissolution rates for augite (at pH > 6), orthopyroxene, pigeonite, and zeolites. In addition, results are affected by the accuracy of models that relate reactions rates, pH, T , and P_{O_2} . Finally, discrepancies between laboratory and natural rates of weathering [*White and Brantley*, 2003; *White*, 2004] question the application of models to complex environments. It follows that presented results should be considered as a step toward investigating the physical chemistry of low-temperature water-rock interactions rather than explicitly solving problems of acid weathering.

3. Results

[19] This section first describes a simulation of weathering of olivine basalt for nominal parameters of the model. We then examine the sensitivity of the model with respect to water/rock (W/R) ratio, initial pH, and atmospheric P_{O_2} . Finally, we model termination of the process through freezing and evaporation of solution at specific stages of weathering.

3.1. A Case Study of Acid Weathering

[20] The modeling was performed for a water/rock mass ratio of unity, original solution pH of 1.2, F_s of 0.01, and partial pressures of O_2 (7.6 μbar) and CO_2 (5.3 mbar) in the present Martian atmosphere. This case may represent weathering of slightly disintegrated basalt. Results demon-

Figure 1. Temporal changes in pH, volumes of primary and secondary minerals, and dissolution rates during acid weathering of olivine basalt. The weathering parameters are: 0°C, 1 bar, the original pH of H₂SO₄-HCl solution is 1.2, $W/R = 1$, $P_{O_2} = 7.3 \mu\text{bar}$, $P_{CO_2} = 5.34 \text{ mbar}$, grain sizes of silicates are 0.2 mm; magnetite, 0.05 mm, and $Fs = 0.01$. In Figure 1c, volumes of minerals are for 1 kg of rock. See color version of this figure in the HTML.

strate partial dissolution of primary minerals, rising pH to 8, and precipitation and dissolution of secondary minerals in time. The volume of primary minerals decreased by 20%, the volume of secondary phases composed 24% of the altered rock, and the total volume (without pores) rose by 7% owing to lower densities of secondary phases (Figure 1a).

[21] When the initial pH is low, primary minerals dissolve fastest (Figure 1b). Rapid dissolution of primary minerals causes partial neutralization of solution, so dissolution rates fall as pH increases. Within the studied pH range, each abrupt increase in pH decreases dissolution rates. As long as the solution remains acidic (at 0°C, neutral pH is 7.48 when $aH^+ = aOH^-$, $K_w = -14.96$), dissolution of olivine strongly affects the composition of solution and neutralization. Weathering of Fe²⁺-bearing pyroxenes is very intense only at pH < ~3. As pH increases, a rapid decrease in dissolution rates of pyroxenes diminishes their alteration. Below pH ~3,

bytownite (i.e., feldspar) dissolves slower than olivine and pyroxene. Although it dissolves as fast as olivine at pH 6–8, the effect of bytownite on solution composition is larger owing to its greater abundance.

[22] Rapid dissolution of pyroxenes at low pH has a major effect because of their large abundance (Figure 1c). At pH 3–5, olivine, bytownite and magnetite, which completely dissolve at some point, are most affected by dissolution. During further weathering, dissolution of bytownite is the major cause for decreasing volume of primary minerals.

[23] Amorphous silica precipitates first and remains the most abundant secondary phase until pH ~6 (Figures 2a and 2b). Goethite forms second and at first stages its formation is mostly attributed to dissolution of magnetite. Formation of clay minerals (kaolinite, Fe²⁺-saponite), consumes excess silica from solution, including SiO₂ supplied from dissolution of previously precipitated silica. Abundant zeolites occur after a long period of time when the solution becomes alkaline. Stellerite (Ca-zeolite) forms first but is replaced by stilbite (Ca-Na-zeolite). Dolomite and Mg-saponite reach saturation at about neutral conditions. Subsequent weathering in alkaline solutions is characterized by increasing amounts of zeolites, clay minerals, and dolomite. Dissolution of plagioclase supplies Na, which is incorporated in clays (Na-saponite and Na-montmorillonite) and stilbite. This example calculation shows that significant periods of time are needed to reach complete neutralization and abundant precipitation of carbonates, zeolites, and smectites.

[24] Composition of aqueous solution (Figure 2c) is controlled by a dynamic balance between dissolution and precipitation. Dissolution of primary minerals increases concentrations of cations and neutral species (e.g., SiO₂) until secondary phases form. Precipitation suppresses the increase of mineralization of solution and may cause a decrease in the concentration of solutes. For example, precipitation of silica and then silicates stabilizes the concentration of SiO₂(aq). Precipitation of goethite, kaolinite, Fe²⁺-saponite and Mg-saponite causes a decrease in concentrations of Fe³⁺, Al³⁺, Fe²⁺, and Mg²⁺, respectively. At pH > ~6, decreasing concentrations of Ca solutes reflect precipitation of zeolites and dolomite. Formation of stilbite and Na-bearing clays stabilize the concentration of Na solutes. Although pH increases with time, precipitation of kaolinite, Fe²⁺-saponite and dolomite stabilizes pH for long periods of time. Overall, solution evolves from Mg-Fe²⁺-Fe³⁺-Al-Ca-CO₂-SO₄-Cl acidic fluid toward an alkaline Na-SO₄-Cl-CO₃ composition, which is mostly controlled by dissolution of plagioclase and precipitation of phyllosilicates, zeolites, and carbonates. Concentrations of HCO₃⁻ and CO₃²⁻ ions increase in time, reflecting increasing solubility of atmospheric CO₂ at higher pH. In this example, elevated W/R ratio and lack of evaporation and/or freezing prevents deposition of sulfates and chlorides, and concentrations of S⁶⁺-bearing solutes and Cl⁻ do not change.

3.2. Effects of Water/Rock Ratio, Grain Size, Degree of Exposure, Initial pH, and O₂ Pressure

[25] Modeling shows that patterns of pH change and sequence of mineral precipitation are not strongly affected by the water/rock mass ratio in the range of 0.01–100

Figure 2. (a, b) Volumes of secondary minerals and (c) the composition of aqueous solution during acid weathering of olivine basalt. Different vertical scales are used in Figures 2a and 2b. Parameters of alteration are described in the caption of Figure 1. In Figure 2c, concentration of dissolved O_2 is $\sim 1.6 \times 10^{-8}$ mol kg⁻¹. $\Sigma CO_2 = \Sigma(CO_2, HCO_3^-, CO_3^{2-}, CaHCO_3^+, MgHCO_3^+)$; $\Sigma S^{6+} = \Sigma(SO_4^{2-}, HSO_4^-, MgSO_4, CaSO_4, NaSO_4^-)$; $\Sigma Mg = \Sigma(Mg^{2+}, MgSO_4, MgHCO_3^+, MgHSiO_3^+)$; $\Sigma Ca = \Sigma(Ca^{2+}, CaSO_4, CaHCO_3^+)$; $\Sigma Fe^{2+} = \Sigma(Fe^{2+}, HFeO_2^-)$; $\Sigma Na = \Sigma(Na^+, NaSO_4^-, NaHSiO_3)$. See color version of this figure in the HTML.

where “water” represents H_2SO_4 -HCl solution. Rates of dissolution are not directly influenced by W/R ratio. However, W/R ratio influences the timing of neutralization and saturation of solution with respect to secondary phases. For some minerals (silica, kaolinite, Fe^{2+} -saponite), time of precipitation is roughly proportional to W/R ratio. At the same original pH, higher W/R ratios cause slower neutralization and late precipitation of secondary minerals (Figures 3 and 4). In contrast, low W/R ratios cause faster neutralization and can lead to a diverse assemblage of secondary minerals during short-duration acid weathering. Weathering at small W/R ratios also causes precipitation of some minerals (daphnite, siderite, calcite) that do not form at elevated W/R . However, in these cases, amounts of secondary phases are small and most of the initial minerals remains unaltered. Evidently, weathering is fastest if a small amount of low-pH solution interacts with completely exposed dust-size particles (Figure 4).

[26] Increasing grain sizes and decreasing mineral exposure produce smaller effective surface areas and lead to similar effects as an increase in W/R ratio. Timing of neutralization and deposition of major secondary phases is proportional to primary mineral grain sizes (Figure 5). However, at small grain sizes, some secondary minerals (dolomite, daphnite, siderite) tend to precipitate earlier at lower pH. Timing of secondary deposition is proportional to the degree of grain exposure with the exception of daphnite, dolomite, and Mg-saponite, which form relatively early at lower pH near well-exposed mineral grains ($F_s > 0.1$), as can be seen in Figure 6. Daphnite may not precipitate during weathering of grains with diameter $> \sim 0.1$ mm, at low degrees of exposure, and at high W/R ratios (Figures 2–6). However, daphnite is the major ferrous phyllosilicate that forms through weathering of fine particles by low amounts of acid fluids, which may represent acids attacks on typical Martian soil (Figure 7).

Figure 3. (a) Effects of initial water/rock mass ratio on pH and (b) secondary mineralogy during acid weathering of olivine basalt. Other parameters of weathering are the same as for Figure 1. In Figure 3a, grey dashed lines with arrows show precipitation conditions of some minerals. In Figure 3b, horizontal lines depict time intervals at which minerals are present in altered rocks at different W/R ratios. See color version of this figure in the HTML.

[27] Initial solution pH has a moderate effect on the general sequence of mineral precipitation, but significantly affects timing of precipitation and neutralization. Weathering by solutions with initial pH of 0–2 causes very early precipitation of amorphous silica followed by the formation of gypsum (Figure 8). Higher initial pH causes later precipitation of silica and earlier formation of goethite, phyllosilicates and carbonates. If original pH > 2–3, amorphous silica does not form and aluminosilicates precipitate earlier than in systems with lower original pH. If original

pH > ~2, goethite can form before silica. Goethite precipitates earlier at higher initial pH.

[28] Variations in P_{O_2} affect pH, timing of mineral precipitation, and amounts of goethite and ferrous aluminosilicates as illustrated in Figures 9 and 10. At $P_{O_2} < \sim 10^{-4}$ bar, which characterizes present and past Martian surface conditions, formation of goethite is accompanied by deposition of ferrous phyllosilicates (Fe²⁺-saponite, daphnite). Siderite can also form at late stages of weathering of fine particles at low W/R ratios and then subjected to dissolution (and oxidation) (Figures 4, 5b, and 7a). At $P_{O_2} < \sim 10^{-7}$ bar formation of goethite is mostly accounted for by the supply of Fe³⁺ from dissolving magnetite (Figures 9 and 10). At the P_{O_2} of present Martian atmosphere ($\sim 10^{-5}$ bar), only minor amount of goethite forms if magnetite is not present (Figures 7b and 9).

[29] Formation of nontronite, a Fe³⁺-bearing smectite, has not been observed. Formation of ferric aluminosilicates requires a specific array of activities of Fe³⁺, Al³⁺ and SiO₂(aq), which is probably less likely than reaching saturation with respect to ferric hydroxide. Formation of K-Na-H₂O jarosites have not been observed. Formation of jarosite requires low W/R ratios [e.g., Zolotov and Shock, 2005] that do not represent many of our models. These results demonstrate that goethite is more stable than jarosite. Observed precipitation of goethite instead of hematite is consistent with higher stability of goethite in low-temperature solutions that have high (~1) activity of water.

3.3. Freezing and Evaporation of Weathering Solutions

[30] We modeled equilibrium freezing of typical solutions that represented various stages of acid weathering (Table 3).

Figure 4. Effects of water/rock mass ratio on time of secondary precipitation during acid weathering of basaltic dust. The dust is presented by 10-micron monomineral silicate particles and 2.5-micron magnetite grains that are fully exposed to solution. Other parameters of weathering are the same as for Figure 1. The dashed lines correspond to time at which specific pH is achieved. The lines with arrows show times of first deposition of secondary minerals. The arrows point toward field of conditions at which secondary phases form. Note that siderite dissolves at higher pH and the grey line shows the conditions of its complete dissolution. See color version of this figure in the HTML.

Figure 5. Effect of grain size of primary minerals of olivine basalt on timing of neutralization and deposition of secondary minerals during acid weathering. (a) One percent of mineral grains is exposed for solution ($F_s = 0.01$). (b) Particles are fully exposed to solution ($F_s = 1$). Other parameters are the same as for Figure 1. The dashed lines correspond to time at which specific pH is achieved. The lines with arrows show times of first deposition of secondary minerals. The grey curve shows the conditions of complete dissolution of siderite. The grain size on x axis corresponds to the diameter of spherical silicate grains, the diameter of magnetite grains is 4 times less. The double arrow shows the range of particle size in Martian soils from Ferguson *et al.* [2006]. The grain size of the atmospheric dust is 0.2–10 micron. See color version of this figure in the HTML.

Complete freezing of acidic solutions leads to the formation of abundant hydrated Mg sulfates, hydrated Mg chloride, gypsum, and silica. Freezing of solutions with initial $\text{pH} < \sim 5.5$ causes deposition of melanterite, $\text{FeSO}_4 \cdot 7\text{H}_2\text{O}$. The formation of ferrous sulfate reflects the predominance of Fe^{2+} over Fe^{3+} in solutions (except very early stages of weathering, Figure 2c). Freezing of solution with $\text{pH} \sim 7$ causes precipitation of tiny amounts of siderite and hydro-magnesite. Sodium sulfate (mirabilite) and chloride (hydrohalite) become increasingly abundant precipitants from initial solutions with higher pH, which represent advanced

stages of weathering. Freezing of slightly alkaline fluids causes precipitation of abundant Na salts (mirabilite, natron, hydrohalite) while Mg sulfates and chlorides do not form. The deposition of abundant carbonates from alkaline solutions is accounted for by increased solubility of atmospheric CO_2 . Compared to high-pH solutions, the amounts of precipitated hydroxides and/or oxyhydroxides of Fe^{3+} and Al^{3+} are significantly larger during freezing of fluids with pH below ~ 2 and ~ 4 , respectively.

[31] The sequence of precipitation during freezing reflects the solubility of solids and initial solution composition. An early precipitation of gypsum, SiO_2 , Fe^{3+} and Al^{3+} hydroxides, and carbonates (from high-pH solutions) is followed by the formation of Mg and Fe sulfates and then Mg and Na chlorides (Figure 11a and Table 3). Although sulfate and chloride ions have a tendency to accumulate in the aqueous phase, evolution of solution composition reflects the pattern of precipitation (Figure 11b).

[32] Freezing of acid fluids is accompanied by the accumulation of protons in solution that may lead to the formation of acid hydrates and acid salts at eutectics. For example, freezing of solution with pH 1.6 causes formation of solid H_2SO_4 hydrate, which is more abundant than Mg sulfate (Figure 11a and Table 3). An exotic Na sulfate, $\text{Na}_3\text{H}(\text{SO}_4)_2$, forms at pH -1.26 . The calculated eutectic temperature, at which $\text{H}_2\text{SO}_4 \cdot 6.5\text{H}_2\text{O}$ forms, is -64.4°C , close to the average temperature of Martian surface (-63°C). High concentrations of H^+ in our initial solutions could be primarily responsible for lowering eutectic temperatures. Higher initial pH causes freezing at higher temperatures (Table 3).

[33] Evaporation of acid solutions at 0°C leads to the formation of abundant hydrated Mg sulfate (epsomite), Fe^{2+} salts (melanterite), and Ca sulfates (Figure 12). Evaporation

Figure 6. Effect of exposure of primary mineral grains (F_s) of olivine basalt on timing of neutralization and deposition of secondary phases. Other parameters of weathering are the same as for Figure 1. Parameter F_s is taken to be the same for all minerals. The dashed lines correspond to time at which specific pH is achieved. See color version of this figure in the HTML.

Figure 7. Volumes of secondary phases and pH during acid weathering of fine olivine basalt sand at $W/R = 0.1$ and complete exposure of particles to solution. Grain size of silicates is 100 micron; magnetite, 25 micron. The grain size of silicates is typical for Martian soil [Ferguson et al., 2006] and represents the most wind-movable grain fraction [Greeley et al., 1980]. In Figure 7b, dissolution of magnetite was suppressed to illustrate weathering of basalt without magnetite. Other parameters are the same as for Figure 1. Note that silica precipitates very early (in ~ 2 hours) and that very small volumes of secondary phases form. Comparison of Figures 7a and 7b indicates a major contribution of magnetite weathering in goethite formation. See color version of this figure in the HTML.

of solution with pH 1.61 causes decrease in pH below -1 and preferential accumulation of Cl^- and SO_4^{2-} in solution. Modeling shows a tendency for dehydration of early formed sulfates in very concentrated solutions. However, the fate of concentrated acid solution is unclear because of high $a\text{H}^+$ and the uncertainty of thermodynamic data for $\text{H}_2\text{SO}_4 \cdot 4\text{H}_2\text{O}$ at 0°C [Marion, 2002]. Current data do not exclude that $\text{H}_2\text{SO}_4 \cdot 4\text{H}_2\text{O}$ is stable among phases formed at complete evaporation. Note that our models refer to evaporation and freezing of solution that does not interact

Figure 8. Temporal changes in pH during weathering of olivine basalt for solutions with various initial concentrations of H_2SO_4 and HCl . Other parameters are the same as for Figure 1. Numbers at each curve corresponds to the molar amount of H_2SO_4 per kg of water in original solutions. For each solution, $\text{H}_2\text{SO}_4/\text{HCl}$ molar ratio is 5.2. Dashed lines show pH and time of first precipitation of some minerals. Arrows at these lines point toward field of conditions at which minerals form. See color version of this figure in the HTML.

Figure 9. Volumes of secondary goethite and pH during acid weathering of olivine basalt at various partial pressures of O_2 . Other parameters are the same as for Figure 1. Mars surface conditions are represented by $P_{\text{O}_2} = 7.3 \mu\text{bar}$, Mars subsurface or “volcanic” atmosphere is characterized by $P_{\text{O}_2} < \sim 10^{-7}$ bar, and Earth’s surface conditions correspond to $P_{\text{O}_2} = 0.2$ bar. The grey curve shows the volume of goethite that forms at current Martian P_{O_2} if magnetite is not present. Goethite does not form before time of 10 years; the time interval of 10–100 years is characterized by the formation of a tiny amount of goethite through dissolution of magnetite. After $\sim 10^2$ years, the formation of goethite occurs via the dissolution of magnetite and aqueous oxidation of Fe^{2+} . Dissolution of magnetite provides the major source of goethite at current Martian P_{O_2} . See color version of this figure in the HTML.

Figure 10. Volumes of (a) goethite and (b) Fe^{2+} -saponite and daphnite formed during acid weathering of olivine basalt as functions of P_{O_2} . Other parameters are the same as for Figure 1. Each curve represents different time since the beginning of acid weathering. The vertical dashed lines show P_{O_2} in present Mars' and Earth's atmospheres. In Figure 10a, the triangle depicts the amount of goethite formed by 10^5 years in a magnetite free rock. Below P_{O_2} of $\sim 10^{-7}$, the accumulation of goethite in time is accounted for by the dissolution of magnetite. At elevated P_{O_2} , the increase in goethite volumes in time is also due to oxidation of Fe^{2+} . Ferrous silicates do not form at $P_{\text{O}_2} > 10^{-4}$ bar. At $P_{\text{O}_2} < 10^{-4}$ bar, Fe^{2+} -saponite and daphnite form together with goethite.

with minerals. In the latter case, aggressive low-pH weathering and some neutralization is expected.

4. Discussion

[34] Chemical weathering is seen as an irreversible, nonequilibrium, stochastic process, which implies the necessity of stepwise modeling. At early stages, the process is governed by the dissolution of primary minerals, which remains the limiting step throughout alteration. A pathway of further weathering is governed by a delicate balance between mineral dissolution, precipitation of secondary

phases, and oxidation of Fe^{2+} , which are connected by feedbacks. Dissolution of minerals increases pH, which often leads to lower dissolution rates. Increasing concentrations of solutes causes minerals to precipitate, which can stabilize the composition of solution. Precipitation also regulates pH and dissolution rates. Although higher pH ($> \sim 3.5$) increases the rate of Fe^{2+} oxidation, formation of ferric species releases H^+ (e.g., Reaction 7) partially compensating for rising pH. Significant increases in pH related to the formation of zeolites lowers dissolution rates of ferrous minerals and limits the amount of precipitated goethite.

[35] Despite these compensatory effects, overall decreasing acidity reduces rates of mineral dissolution and makes weathering less efficient in time. A stepwise quasiexponential slowing of weathering can be seen in Figures 1–8. In fact, the major events (formation of amorphous silica, goethite, kaolinite, and smectites) occur early and time intervals between depositions of each new phase grow sequentially. Rapid neutralization and corresponding decrease

Figure 11. (a) Precipitation of solids and (b) concentrations of aqueous species during equilibrium freezing of the solution formed at an early stage of acid weathering of olivine basalt. The starting solution containing 1 kg of water (55.508 moles) corresponds to the time of 10.1 years at Figure 2c and has pH 1.61. The dashed vertical lines correspond to eutectic temperature. The eutectic composition is also shown in Table 3. See color version of this figure in the HTML.

^aCompositions of solutions correspond to different stages of acid weathering of olivine basalt for the nominal model with initial solution pH of 1.2 (Figure 2c). Solution pH 1.61, 4.17, and 7.03 correspond to times 10.1, 90.4, and 9115 years since the beginning of acid weathering, respectively. Solids form below the indicated temperatures until the temperature of eutectic. For solution with pH 1.61, changes in amounts of solids and solution composition during freezing are shown in Figure 11.

^bData for SiO₂, FeOOH, and Al(OH)₃ that represent oxides, hydroxides, and oxyhydroxides of Si, Fe³⁺ and Al were obtained without equilibrium calculations. Because of low solubility, these species could precipitate before gypsum.

^cMirabilite forms until −34°C (max volume is 0.19 cm³) where it is replaced by hydrohalite.

^dHydrohalite forms until −40.2 (max volume is 0.03 cm³) where it is replaced by mirabilite.

Figure 12. (a) Amounts of precipitated solids and (b) concentrations of aqueous species during incomplete equilibrium evaporation (at 0°C) of the solution formed at an early stage of acid weathering of olivine basalt. The starting solution is the same as for Figure 11. Although further evolution of solution is not shown (see text), it may include dehydration and dissolution of precipitates at extremely low pH. See color version of this figure in the HTML.

in dissolution rates work toward preservation of primary minerals. For typical basaltic lava, a complete closed system equilibration at low-temperature aqueous conditions could not be achieved even over geological timescale (Figures 1–3). Short-term episodes of acid weathering do not affect the majority of large rock fragments and the process may end before precipitation of clays, zeolites, and carbonates. This inference is strengthened by typically lower rates of natural weathering compared to laboratory data [e.g., *White and Brantley*, 2003] used in modeling.

4.1. Fate of Primary Minerals in Weathering Models and Martian Materials

[36] Different pH dependencies of mineral dissolution rates (Table 2) imply preferential dissolution of specific primary phases at each weathering stage (Figure 1b). It follows that abundances of primary minerals in a weathered material could reflect a stage of alteration. Our results show that basalt weathered below pH ~ 3 would be enriched in plagioclases that dissolve slower than olivine, Fe-Mg pyroxenes and magnetite.

[37] On the Martian surface, variations in abundances of primary basaltic minerals could reflect preferential dissolu-

tion of some phases. The interpretation of thermal emission spectra (TES) of low-albedo surface regions reveals broad variations in the pyroxene/plagioclase ratio (0.16 to 1.24) [Bandfield et al., 2000; Bandfield, 2002; Hamilton et al., 2001; Wyatt and McSween, 2002; McSween et al., 2003; Michalski et al., 2006a; Rogers et al., 2007], which may not be entirely related to igneous petrology. Lowest pyroxene/plagioclase ratios are observed in the Northern hemisphere, for example, in Acidalia Planitia (surface type 2 [Bandfield et al., 2000; Bandfield, 2002; Christensen et al., 2001a]). These observations are consistent with faint pyroxene features in near-infrared spectra of northern low-albedo regions [Bibring et al., 2005; Mustard et al., 2005; Mustard and Cooper, 2005]. A kinetic modeling in the pyroxene-plagioclase system open to solution [McAdam et al., 2007a], and our results suggest that the observed deficiency of pyroxene could be related with aqueous weathering below pH 3. In Gusev crater, depletion of rock surfaces in Mg and Fe in the Clovis class rocks may indicate preferential low-pH dissolution of pyroxene and olivine relative to feldspars [Hurowitz et al., 2006]. In heavily altered Wishstone class rocks, the high Na-plagioclase/pyroxene ratio (4–5 [Ruff et al., 2006]) may reveal faster dissolution of pyroxene. A presence of plagioclase in heavily altered jarosite-bearing bedrocks in Meridiani Planum [Glotch et al., 2006] also agrees with its slow low-pH alteration compared to primary Fe-Mg silicates that are not detected in the bedrocks. A high plagioclase/pyroxene ratio inferred from TES spectra of Martian dust [e.g., Bandfield and Smith, 2003] is also consistent with preferable pyroxene alteration (A. C. McAdam et al., Preferential low-pH dissolution of pyroxene in plagioclase-pyroxene mixtures: Implications for Martian surface materials, submitted to *Icarus*, 2007). Since the spectral data refer to surfaces on mineral grains, the bulk pyroxene/plagioclase ratio in surface materials may not be strongly affected by weathering. It is possible that observed weak pyroxene signatures are related to specifics of surface alteration of pyroxene and/or silica coatings [Rampe et al., 2006] (see section 4.2).

[38] The presence of magnetite in Martian soil [Morris et al., 2006] and atmospheric dust [Pollack et al., 1979; Goetz et al., 2005] is not consistent with weathering above pH 3–5 when magnetite may dissolve faster than silicates (Figure 1b). Weathering of magnetite could have been slowed because of a presence of Ti [White et al., 1994], a resistance to physical weathering, and secondary Fe^{3+} oxide coatings, consistent with reddish hue of magnetite-rich dust particles accumulated on MER magnets [Goetz et al., 2005].

4.2. Secondary Silica

[39] The models show that formation of amorphous silica may designate early stages of basalt weathering by solutions with initial pH below ~ 3 . Neutralization of these solutions above pH 3 may cause dissolution of silica. Our results agree with the formation of amorphous silica in experiments aimed to model acid weathering of basalts [Tosca et al., 2004; Golden et al., 2005; Hurowitz et al., 2005] and at volcanic locations affected by acid vapors and solutions [Golden et al., 1993; Wolfe et al., 1997; Morris et al., 2000; Schiffman et al., 2006]. An early formation of silica is also inferred from thermodynamic models for acid weathering [Schiffman et al., 2006; McAdam et al., 2007b]. These

observations and models are consistent with low solubility and slow dissolution of amorphous silica in acids [Dove and Rimstidt, 1994; Dove, 1995].

[40] Secondary silica has been reported in the ALH84001 Martian meteorite where it forms veins and coatings probably deposited from low-*T* aqueous solutions [Westall *et al.*, 1998; McKay *et al.*, 1998]. A likely presence of amorphous silica in surface materials became evident from thermal infrared spectra obtained from the orbit and at MER sites. Indistinguishable “high-silica phases” observed in spectra of some low-albedo regions (surface-type 2) may contain amorphous silica formed through basalt alteration [Wyatt and McSween, 2002; Kraft *et al.*, 2003; Michalski *et al.*, 2005]. Laboratory investigations show that thermal infrared observations could be explained by silica coating on primary mineral grains [Kraft *et al.*, 2003; Rampe *et al.*, 2006]. Abundant (up to 25 vol.%) silica-rich glass and/or impure amorphous silica in layered bedrocks in Meridiani Planum [Glotch *et al.*, 2006] is consistent with acid environments. At the Columbia Hills in Gusev crater, some rock classes (Clovis, Watchtower) may contain high-silica glass [Ruff *et al.*, 2006] that may represent weathering products. The elemental composition of trench soils in Gusev crater indicates a presence of silica [Haskin *et al.*, 2005]. At the Mars Pathfinder landing site, elevated Si content in rock fragments may represent secondary silica on basaltic rock fragments [McLennan, 2003; Hurowitz *et al.*, 2006] that contributes to the observed “andesitic” bulk composition [Foley *et al.*, 2003]. If confirmed, the presence of amorphous SiO₂ in Martian surface materials would be consistent with low-pH environments and a lack of thorough neutralization of aqueous solutions in many locations.

[41] Since the formation of silica coatings on primary minerals decreases their dissolution rates, chemical or mechanical removal of coatings could be needed to facilitate alteration. Silica coatings could be weakened through neutralization of solution, alteration by solution with pH > 3, as well as physical weathering during and between episodes of aqueous weathering. Note that experimental data [Tosca *et al.*, 2004; Golden *et al.*, 2005; Hurowitz *et al.*, 2006] and field observations [Schiffman *et al.*, 2006] do not reveal a significant lingering of acid weathering because of silica coating.

4.3. Fate of Ferrous Iron During Martian Weathering

[42] Ferrous minerals on the Martian surface have been subjected to irreversible but limited oxidation. Although Martian surface materials contain several ferric phases (nanophase oxides, goethite, hematite, jarosite, and nontronite [Morris *et al.*, 2000, 2006; Klingelhöfer *et al.*, 2004; Poulet *et al.*, 2005; Glotch *et al.*, 2006]), ferrous minerals typically dominate in rock fragments and soils. The presence of magnetite in dust [Pollack *et al.*, 1979; Goetz *et al.*, 2005] and soil [Morris *et al.*, 2006], and olivine and pyroxenes in rock fragments and soils [e.g., Klingelhöfer *et al.*, 2004; Morris *et al.*, 2006; Mustard *et al.*, 2005; Hoefen *et al.*, 2003] are consistent with only partial oxidation of primary minerals. Throughout history, aqueous Fe²⁺ oxidation at the surface could have been restricted by rare and short appearances of aqueous solutions [Haberle, 1998], and slow oxidation in acidic and O₂-deficient environments [Burns, 1993; Hurowitz *et al.*, 2006] (see also our

results). Likewise, anhydrous photooxidation of ferrous minerals could have not been efficient [Morris and Lauer, 1980].

[43] At $P_{O_2} < \sim 10^{-7}$ bar, which could represent Martian atmosphere during active volcanism [Catling and Moore, 2003], the role of Fe²⁺ oxidation is negligible and dissolution of Fe³⁺ spinels provided the major source for secondary Fe³⁺ species. The incongruent dissolution of magnetite in acid solutions leads to the formation of metastable maghemite [White *et al.*, 1994],

followed by its conversion to stable goethite or hematite (at low $a_{H_2O(l)}$ and in anhydrous conditions in the equatorial region). A paucity of magnetite in primary rocks (as in several Martian meteorites) makes formation of secondary Fe³⁺ phases entirely dependent on oxidation that becomes efficient only at elevated pH and P_{O_2} .

[44] Our results demonstrate that Martian acid weathering supplies Fe²⁺ in solution faster than it oxidizes by dissolved O₂. This may cause precipitation of ferrous phyllosilicates (smectites and chlorites), as well as deposition of ferrous sulfates and chlorides during freezing and/or evaporation. If solution does not freeze or evaporate in O₂-deficient conditions ($P_{O_2} < \sim 10^{-4}$ bar), formation of ferrous phyllosilicates consumes Fe²⁺ from solution, delays its neutralization, decreases Fe²⁺ oxidation rate, and leads to smaller amounts of goethite compared to acid weathering at O₂-rich Earth-like conditions (Figures 9 and 10). A rapid supply of Fe²⁺ in solution during weathering of fine particles at low *W/R* ratios can cause deposition of daphnite and siderite (Figures 4–7). Overall, our models demonstrate that short-time episodes of acid weathering on Mars should not cause significant oxidation, especially at current P_{O_2} .

[45] In addition to short duration of O₂-rich periods, oxidation could be limited by Fe³⁺-oxide coatings that restrict dissolution of primary and secondary ferrosilicates, as it happens on Earth. An early deposition of silica and Fe³⁺ hydroxide during freezing/evaporation of acid solutions would also lead to protective coatings. It is possible that ferric oxide (and silica?) coatings on magnetite dust particles [Goetz *et al.*, 2005] prevented thorough oxidation of the mineral.

[46] A prolonged single acid weathering episode on Mars could have led to deposition of mostly ferrous phases: sulfates, chlorides, smectites, chlorites, and siderite, while formation of goethite was mainly related to dissolution of magnetite. Subsequent weathering events would first cause dissolution of ferrous salts and make Fe²⁺ available for oxidation. Dissolution of ferrous phyllosilicates, and primary minerals would supply Fe²⁺ ions as well. It follows that irreversible Fe²⁺ oxidation could have occurred through multiple aqueous events in the presence of O₂ in the atmosphere ($P_{O_2} > \sim 10^{-7}$ bar). Aqueous decomposition of H₂O₂, which could be present in the soil [e.g., Yen *et al.*, 2000], provided an additional O₂ source. Oxidation of Fe²⁺-saponite could have led to formation of nontronite that is tentatively detected in small surface regions [Poulet *et al.*, 2005] and layered rocks at Meridiani Planum [Glotch *et al.*, 2006]. Although oxidation of Fe²⁺-saponite to poorly crystalline nontronite occurs on Earth [Kohyama and Sudo,

1975], efficiency of Martian oxidation of saponite is limited by low P_{O_2} and a necessity of advanced Mg leaching from octahedral sites.

[47] Formation of significant amounts of Fe^{3+} compounds, as in hematite-rich regions [Christensen *et al.*, 2001b], requires the involvement of significant masses of O_2 , which are comparable with the atmospheric abundance. These masses of O_2 may not be related to periods of active volcanism [Catling and Moore, 2003] but could have been produced in large impacts (see section 4.5).

4.4. Dust Weathering, Weathering Rinds, and Specifics of Northern Lowlands

[48] Martian dust contains an abundant semicrystalline silicate component, as seen in the near-infrared [Soderblom, 1992; Murchie *et al.*, 2000; Bibring *et al.*, 2005] and thermal infrared [Michalski *et al.*, 2006a] spectra of high-albedo surface regions. The dust is not rich in primary minerals (except magnetite, and, probably, plagioclase) but sulfates and chlorides are likely to be abundant. The altered semicrystalline nature of Martian dust (< 10 micron) agrees with rapid acid weathering of small particles (Figures 4 and 5b). Although solution could be neutralized within a year in a closed system, subsequent acid attacks may destroy secondary phases, leading to semicrystalline silicates and Si-, Al-, Fe^{3+} -oxides. Inefficient low-temperature crystallization of phyllosilicates is observed on Earth and suggested for Mars [e.g., Michalski *et al.*, 2006b]. High concentrations of S and Cl in Martian fines could reflect an incorporation of these elements during multiple acid attacks.

[49] Dust particles weather in acid atmospheric aerosols, as a soil component, as well as on surfaces of rocks. In the latter case, weathering would produce a layer of alteration products that contain elements that came from the dust and the rock. Surface layers enriched in Fe^{3+} , S, Cl, and Br on basaltic rocks in Gusev crater may reveal their complex formation [Haskin *et al.*, 2005; Gellert *et al.*, 2006; McSween *et al.*, 2004, 2006; Hurowitz *et al.*, 2006]. As for dust alteration, multiple acid attacks on surface rocks could have prevented formation and accumulation of minerals formed from neutralized solutions. In addition, minerals could be affected by lowering pH during freezing and/or evaporation of solutions (Figures 11 and 12). As a result, silica, Mg-, Fe^{2+} -, and Ca-sulfates and chlorides, amorphous Al-bearing mineraloids (Al-bearing opal [Michalski *et al.*, 2005]), and ferric oxides and sulfates (not modeled here) could compose weathered products on surfaces of basaltic rocks at the end of each weathering episode. The observations of chemically distinct rock surfaces of olivine basalts on plains in Gusev crater [Haskin *et al.*, 2005] agrees with this view. In particular, the lack of evidence for carbonates, smectites, and zeolites on rock surfaces and soils reveals short-term and/or multiple acid attacks.

[50] Abundant Mg sulfates in Martian surface materials are consistent with freezing and/or evaporation of low-pH (< 7.5) fluids formed through acid weathering of basaltic materials. This notion agrees with inferences in recent works [e.g., Tosca *et al.*, 2005; Clark *et al.*, 2005; Hurowitz *et al.*, 2006]. Despite some differences in mineralogy of freezing and evaporation of acid solutions, Martian soil mineralogy may not reveal the leading process of salt precipitation. Although evaporation results in less hydrated

solids than freezing, many salts may then dehydrate to equilibrate with atmospheric H_2O , especially at low latitudes. At present T - P_{H_2O} conditions in the equatorial belt, ice is not stable near the surface, and precipitated salts could dehydrate to $MgSO_4 \cdot H_2O$, $FeSO_4 \cdot H_2O$, $FeCl_2 \cdot 2H_2O$, $MgCl_2 \cdot 2H_2O$, $CaSO_4$, and $NaCl$ [Zolotov, 1989].

[51] Northern low-albedo regions with strong spectral features of “silica-rich phases” and weak pyroxene signal [e.g., Bandfield *et al.*, 2000; Mustard *et al.*, 2005] could have been affected by more intense, and/or longer acid weathering, as well as lower pH solutions compared to equatorial and southern regions, which do not reveal these features. The spectral observations may reflect lower altitude, higher atmospheric pressure, higher atmospheric humidity [Jakosky and Farmer, 1982], larger amounts of ground ice, and more importantly accumulation of surface ice during periods on high obliquity compared to equatorial and southern highlands. All these conditions may cause slower evaporation/freezing, higher W/R ratios, and longer contacts of solution with rocks and soils in northern lowlands.

[52] During periods of high obliquity, acid rock weathering could have occurred through accumulation of acid aerosols and raindrops (see section 4.5) on ice followed by the migration of acid brine pockets toward the ice-regolith boundary. An isolation of acid brine pockets from the atmosphere prevented their evaporation. The low temperature of the H_2SO_4 - H_2O and HCl - H_2O eutectics ($-62^\circ C$ and $\sim -87^\circ C$, respectively) and low water activities (~ 0.8 – 0.5) of low-temperature acid brines allow temporal solution existence near ice even at present climate. During winters, acid brines pockets could have frozen to form H_2SO_4 hydrate (see Figure 11). Melting at warmer seasons favored brine migration toward rocks. Accumulated subglacial aqueous solutions could have led to a prolonged acid alteration of rocks compared to rapidly evaporating (and/or freezing) acid precipitates on ice-free surfaces.

[53] Thermal insulation by thick ice layers could have caused an increase in temperature in lower horizons and also favored downward migration of acid brines and their accumulation at the ice-regolith interface. In addition, this process could have been enhanced by melting at ice-regolith boundaries at low altitudes [Richardson and Mischna, 2005]. This mechanism would cause acid weathering of uppermost regolith layers and is consistent with signs of aqueous migration of silica, and Mg, and Fe^{3+} species observed in rock coatings and excavated soils in Gusev crater [Haskin *et al.*, 2005; Wang *et al.*, 2006b]. Note that melting at the ice-surface interface has been proposed to account for those observations [Arvidson *et al.*, 2004; Haskin *et al.*, 2005].

4.5. Acid Weathering in Martian History: Role of Impacts and Volcanism

[54] Volcanic eruptions and impacts could have been responsible for multiple short-term episodes of acid weathering as a dry and cold climate prevailed over history. The effect of volcanism on generation of acid solutions is mostly attributed to degassing of SO_2 , H_2S , and HCl . However, a consumption of photochemically produced atmospheric oxidants (O_2 , O_3 , OH , and peroxides [Yung and DeMore, 1999]) in reactions with reduced volcanic gases (H_2S , CO ,

H₂, and S₂ [Zolotov, 2003]) would limit the generation of sulfuric acid through oxidation of SO₂ and H₂S. Without photosynthesis, active volcanic degassing could have limited amounts of strong atmospheric oxidants on early Earth [Holland, 1984] and Mars [Catling and Moore, 2003]. Without oxidants, only moderately acid solutions could form because of a limited abundance of volcanic HCl and HF [Symonds *et al.*, 1994; Zolotov, 2003], a mild dissociation of H₂S in solutions ($\text{H}_2\text{S} \rightarrow \text{H}^+ + \text{HS}^-$), and a low solubility of SO₂ compared to SO₃, which forms sulfuric acid. Acid generation through formation of pyrite from dissolved H₂S ($2\text{H}_2\text{S} + \text{Fe}^{2+} \rightarrow 2\text{H}^+ + \text{H}_2 + \text{FeS}_2$) could have been limited by the supply of Fe²⁺ through dissolution of ferrous silicates. Likewise, formation of low-pH fluids would have been limited in the anoxic Martian subsurface. An alkaline nature of Martian subsurface solutions [Zolotov *et al.*, 2004], high concentrations of cations in brines, and low *W/R* ratios would have favored rapid neutralization of volcanic acid gases and fluids. Involvement of photochemical O₂ into oxidation of SO₂ [Settle, 1979] and H₂S, as well as Fe sulfides, provided a major contribution into generation of sulfuric acid, but makes acid weathering a near-surface phenomenon that may not be closely related to volcanism. Finally, volcanic eruptions could not have led to acid raining owing to cold and dry climate throughout history [Haberle, 1998].

[55] Although volcanism was likely to be responsible for the net supply of S and halogens to the Martian surface [e.g., Clark and Baird, 1979; Clark and Van Hart, 1981], the effects of large impacts on aqueous acid weathering and erosion could have been greater than the effects of volcanism. On Earth, the role of impacts in generating acid aerosols and rains has been realized in the context of Chicxulub crater at the Cretaceous-Tertiary boundary [Ivanov *et al.*, 1996; Pope *et al.*, 1997; Pierazzo *et al.*, 1998]. These studies show that the Chicxulub impact into sulfate-bearing sediments released several orders of magnitude more sulfur gases compared to a volcanic eruption. On Mars, the elevated abundance of sulfates in the regolith implies similar effects. Impact generation of SO₂ and/or SO₃ through decomposition of sulfates [Lyons and Ahrens, 1996; Ivanov *et al.*, 1996; Gupta *et al.*, 2001], as well as other oxidized gases (O₂, O₃, NO, NO₂ [e.g., Prinn and Fegley, 1987; Gerasimov, 2002; Gerasimov *et al.*, 2002]) provided reactants to form acids in cooling impact plumes and clouds. Oxidation of sulfides in target and projectile contributed to the release of S-bearing gases. Note that mass independent fractionation of S isotopes observed in Martian meteorites [Farquhar *et al.*, 2000] does not exclude impact degassing and recycling of sulfur through the atmosphere. On the surface, aqueous interaction of strong oxidants with Fe²⁺ and sulfides caused oxidation of S and Fe and produced H⁺. In addition, atmospheric oxidants, which would not be abundant during periods of volcanic activity, would react with impact-generated H₂S, SO₂, and NO to form SO₃ and NO₂, as well as oxidize Fe²⁺ in surface solutions. In H₂O-bearing impact environments, hydrogen halides could form through decomposition of soil halides and igneous chlorapatite, which is abundant in Martian meteorites.

[56] Dissolution of SO₃, H₂S, NO, NO₂, and HCl in water droplets formed through condensation in an impact cloud would have led to an array of acids. Although sulfuric and

hydrochloric acids were probably most abundant, cometary impacts could have led to nitrous and nitric acids [Prinn and Fegley, 1987]. Local and global raining from impact clouds, which is expected in the present climate [Segura *et al.*, 2002], generated acid solutions on the surface. Plentiful impact-generated fine-grained material and silicate glasses would be primarily altered by acid rains/aerosols, consistent with an altered nature of Martian dust and air-blown particles. Acid rainfalls also affected upper surface layers and locally penetrated to deeper horizons upon accumulation in surface depressions. Freezing and/or evaporation of acid solutions led to deposition of sulfates and chlorides. We suggest that sulfate-bearing rocks and soils were a cumulative effect of multiple-impact produced acid volatiles, at least initially from volcanic emissions and impacts on sulfide-rich rocks [cf. Burt *et al.*, 2006].

[57] Penetration of impact-generated acid fluids into surface ice sheets restricted their evaporation and prevented freezing until temperatures of acid-rich eutectics (see Table 3 and Figure 11). During periods of elevated obliquity, subglacial acid weathering by these fluids could have been responsible for the formation of silica-bearing and pyroxene-depleted surfaces in Northern lowlands (e.g., TES surface-type 2 in Acidalia Planitia [Wyatt and McSween, 2002]) and also in middle altitudes in the Southern hemisphere. In addition, these processes could have played a role in the equatorial latitudes, where surface ice could temporary exist at high obliquities.

[58] Impact-generated acid rains could have been responsible for the vertical migration of Si and Fe³⁺ suggested for excavated soils in Gusev crater [Haskin *et al.*, 2005; Wang *et al.*, 2006b]. The elevated abundance of Si and Fe³⁺ observed at depth of ~10 cm [Wang *et al.*, 2006b] may reflect dissolution of surface minerals in low-pH solutions followed by precipitation of silica and Fe³⁺ hydroxide in the shallow subsurface. Acid precipitating from impact plumes may also account for the high abundance of amorphous or semicrystalline material and lack of detection of crystalline phyllosilicates, carbonates, and zeolites in heavily altered rocks at Columbia Hills [Ruff *et al.*, 2006]. This reveals a low-temperature acidic alteration occurred over a limited timescale. The diverse and patchy nature of aqueous processes in Columbia Hills [Ming *et al.*, 2006] could be related to mixing from impact event(s), implying transient involvement of aqueous solutions.

[59] An interaction of heavily altered salt-rich deposits (as in Meridiani Planum [Clark *et al.*, 2005]) with acid rainwater could have not led to rapid neutralization, but increased the amount of salts in deposits. Impact-generated acid rainfalls over proposed impact surge deposits at Meridiani Planum [Knauth *et al.*, 2005] do not contradict with observations and arguments for acidic aqueous conditions [Clark *et al.*, 2005; McLennan *et al.*, 2005] and agree with an addition of S and Cl to basaltic material [McCollom and Hynek, 2005]. A formation of abundant ferric iron phases in layered bedrocks [Klingelhöfer *et al.*, 2004; Glotch *et al.*, 2006] could have been driven by plentiful impact-generated oxidants. A possibility exists that the deposition of impact surge deposits and low-pH aqueous processes were related to a large single impact in Meridiani Planum.

[60] In addition to our earlier suggestions, a large degree of rock alteration and/or elevated silica content in northern

low-albedo regions [Wyatt and McSween, 2002; Kraft *et al.*, 2003; Michalski *et al.*, 2005] could be related to impact degassing of more abundant ground ice, sulfate, and other hydrated salt deposits as compared to equatorial and southern highlands. Finally, a correlation of P with S and Cl observed in MER sites could be explained by multiple acid rainfalls that delivered S and Cl and favored P mobility [Greenwood and Blake, 2006].

[61] A high impact rate in Noachian implies an efficient acid weathering followed by surface erosion, aqueous transport, and deposition of salts and suspended particles in temporal water reservoirs. In fact, Segura *et al.* [2002] show that impact-generated rainfalls could have been responsible for the high erosion rate in Noachian time [cf. Craddock and Howard, 2002] and the formation of valley networks. No warm and wet climate is needed for impact-induced exogenic processes. It follows that a majority of aqueous oxidation, formation of silica, and Mg-Fe-Ca sulfates could have occurred in the earliest period of geological history.

[62] With or without a warm and wet climate, frequent large impacts in Early Noachian caused stronger rainfalls and longer duration of weathering episodes compared to subsequent epochs. Warm/wet climate would have reduced the impact of acid weathering because of dilution of acids in persistent and neutralized surface water reservoirs. The longer duration of weathering episodes favored partial and/or local neutralization in temporal surface water reservoirs. A presence of tentatively detected nontronite in Meridiani Planum [Glotch *et al.*, 2006] may reflect neutralization that facilitated the growth of Fe^{3+} oxide concretions [Zolotov and Shock, 2005]. The neutralization could have been slowed because of accumulation of H^+ through freezing/evaporation (Figures 11 and 12), a conversion of jarosite to goethite, the absence of rapidly dissolving pyroxenes and olivine, and possible silica/ Fe^{3+} -oxide coatings. At Columbia Hills, an existence of poorly crystalline [Ruff *et al.*, 2006] kaolinite-type aluminosilicates in some Clovis class rocks indicates mildly acidic conditions [Wang *et al.*, 2006a] ($\text{pH} > \sim 3.5$, see Figure 2), which may imply some neutralization of original acid solutions.

[63] In other locations, more advanced neutralization could have occurred. An evaporitic formation of carbonates in the ALH85001 Martian meteorite [Warren, 1998] about 3.9–4.0 Ga ago implies nonacidic pH, which may also reflect neutralization at some depth. The only local occurrence of smectite deposits [Poulet *et al.*, 2005] in Noachian-age regions indicates spatially limited neutralization. Using terrestrial analogues, the formation of observed layered clay deposits could have occurred through surface weathering followed by aqueous transport in suspension and accumulation in water reservoirs. A massive nature of Noachian clay deposits and low permeability could have limited their weathering by subsequent acid attacks. To conclude, acid weathering in Noachian probably played a larger role compared to subsequent epochs, though achieved larger degrees of neutralization because of longer existence of surface solutions and their temporal accumulation in surface reservoirs, where clays deposited. Although the intensity of impact-induced acid weathering declined in time, low-pH aqueous processes could have also been important during the Hesperian epoch, when volcanism reached its highest

levels in history [Tanaka *et al.*, 1992] and large impacts still occurred.

5. Summary

[64] 1. Kinetic-thermodynamic modeling of acid weathering of olivine basalt in a closed system reveals a time-dependent sequence of mineral precipitation and evolution of solution composition. Results demonstrate preferential dissolution of olivine and pyroxenes at low pH followed by predominant dissolution of plagioclase at higher pH. Solution evolves from acidic Mg-Fe-rich compositions toward Na-rich alkaline fluids. Early low-pH stages of weathering are characterized by the formation of amorphous silica and ferric hydroxides/oxyhydroxides formed through dissolution of magnetite. Formation of smectites, carbonates, and zeolites requires major neutralization and takes significantly more time than the deposition of silica. Inefficient Fe^{2+} oxidation under low-pH and O_2 -deficient conditions causes precipitation of secondary ferrous phases. Neutralization and mineral precipitation occur faster at higher solution pH, lower W/R ratios, and larger surface areas of exposed materials. Although short episodes of acid weathering cannot lead to significant alteration of rocks, dust-size particles could be altered within hours.

[65] 2. The comparison of models with Martian surface data reveals multiple episodes of acid sulfate weathering that rarely led to neutralization of solution and ceased because of freezing and/or evaporation. This notion is supported by (1) the likely presence of amorphous silica, Fe^{3+} -secondary phases, semicrystalline silicates, and abundant Mg sulfates in surface materials, (2) faint spectral features of pyroxene in northern low-albedo regions, dust, and MER sites, (3) the occurrence of primary minerals in soil and dust, and (4) a lack of widespread and abundant smectites, zeolites, and carbonates.

[66] 3. Freezing of Martian $\text{H}_2\text{SO}_4\text{-HCl}$ acid solutions could have caused the deposition of abundant Mg sulfates and Fe^{2+} salts, a decrease in pH, and the formation of sulfuric acid hydrate at low-temperature eutectics ($\sim 60^\circ\text{C}$). If isolated from the atmosphere (e.g., in ice), acid eutectic solutions could exist at the average surface temperature of present Mars and may contribute into acid weathering of subglacial materials.

[67] 4. Generation of O_2 and other oxidants, decomposition of sulfates, and oxidation of sulfides through strong impacts could have provided a major source of sulfuric acid throughout Martian history. The formation of impact-generated acid rains and aerosols may account for signs of acid weathering in Gusev crater, Meridiani Planum, the Mars Pathfinder landing site, as well as for silica-rich phases and a pyroxene deficiency observed in northern low-albedo regions. The formation of strong oxidants by impacts could have mainly contributed to aqueous oxidation of Fe^{2+} that was inefficient during periods of volcanism. Despite slow oxidation at low pH, large impacts led to incremental oxidation of Fe^{2+} released from primary minerals and previously formed secondary ferrous phases. Volcanic generation of acids could have been important during Hesperian time but limited by the photochemical production of atmospheric oxidants.

[68] 5. Although impact-generated acid rainfalls could have caused intense weathering and erosion in Noachian time, dilution of acids and a prolonged existence of surface aqueous solutions favored local neutralization of solution, and formation, aqueous transport and deposition of clay minerals in water reservoirs.

Notation

a	activity of a solute.
ΔG	Gibbs free energy of reaction, J mol ⁻¹ .
E_a	apparent activation energy, J mol ⁻¹ .
F_{S_i}	fraction of mineral surface exposed to solution.
K_{0H+}	rate constant for dissolution at pH below pH of zero charged surface at 298.15 K.
K_{0H2O}	rate constant for dissolution at pH of zero charged surface at 298.15 K.
K_{0OH-}	rate constant for dissolution at pH above pH of zero charged surface at 298.15 K.
K_w	ionic product of water.
P_j	partial pressure of gas, bar.
R	gas constant, J mol K ⁻¹ .
r_i	rate of mineral dissolution, mol m ⁻² s ⁻¹ .
R_i	radius of spherical mineral grains, m.
S_i	mineral surface area exposed to aqueous solution, m ² .
T	absolute temperature, K.
T_0	standard temperature (298.15 K).
V_i	volume of mineral grains, m ³ .
W/R	water to rock mass ratio.
x_i	molar amount of mineral (i) dissolved at each time step.
Δt	duration of current time step, s.

[69] **Acknowledgments.** We thank Venyamin B. Polyakov for helpful discussions and advice and Viktor A. Alekseev for sharing preprints on kinetics of mineral dissolution. We also appreciate Amy McAdam for reviewing some data on mineral dissolution. This work benefited from discussions with Amy McAdam, Christopher Glein, and Everett Shock and comments from them. We thank Giles Marion for the constructive review.
